Interacting with other languages
Calling out to C/C++
Meta programming
Manipulating variables
Manipulating code expressions / ASTs

Interacting with other languages

Student presentations cover interaction with Python and Julia.

Calling out to C/C++

We can call C (and presumably C++) functions.

Here's an example in which we'll call the dnorm4 function in the R math library, which is the C function used by R's dnorm function, which returns the log density.

```
x = 0
mu = 10
sd = 1
dev = @ccall "/usr/lib/libRmath.so".dnorm4(x::Cdouble,mu::Cdouble,sd::Cdouble)::Cdouble;
print(dev)
```

-50.918938533204674

Perhaps the use of C code related to R is a bit confusing, but the key things here are to point <code>@ccall</code> to a shared object/dynamically linked library file (.so on Linux/MacOS, presumably .dll on Windows) that contains the compiled code for the function you want to use and to provide input and output types as indicated above.

To investigate further, we'd want to look into passing pointers to allow for handling arrays.

Meta programming

Julia has powerful functionality for using code to actually manipulate and run Julia code. This is called meta programming (sometimes also called *computing on the language*) and is something one can also do in R. I'm not sure how much of this one can easily do in Python.

We'll just crack the surface here.

Manipulating variables

```
num = 3
varname = "x" * string(num)
var = Meta.parse(varname) # One way to create the variable as a `Symbol` object.
var
:x3
var2 = Symbol(varname) # Another way.
typeof(var)
Symbol
value = 7
mycode = quote
 $var = $value
end
xЗ
LoadError: UndefVarError: `x3` not defined
UndefVarError: `x3` not defined
mycode
quote
    #= In[5]:4 =#
    x3 = 7
end
value = 23;
eval(mycode);
xЗ
value = 9;
mycode = quote
 $var = value
end
```

```
mycode
quote
    #= In[8]:3 =#
    x3 = value
end
value = 23;
eval(mycode);
xЗ
23
Manipulating code expressions / ASTs
We can create and manipulate code expressions.
textcode = "a+b"
expr1 = Meta.parse(textcode)
expr2 = :(a+b)
expr3 = Expr(:call, :+, :a, :b)
print(expr1 == expr2)
print(expr1 == expr3)
typeof(expr1)
truetrue
Expr
expr1.args
3-element Vector{Any}:
 :+
 :a
 :b
a=7
b=3
eval(expr1)
10
Let's modify the expression!
expr1.args[1] = :*
print(expr1)
```

a * b

```
eval(expr1)
21
Remember ASTs (abstract syntax trees?
expr = :(tan(x) + 3 * sin(x))
expr.args
3-element Vector{Any}:
 :(tan(x))
 : (3 * \sin(x))
expr.args[3]
:(3 * sin(x))
We have access to the full AST!
expr.args[3].args[2]
3
And we could modify the AST as shown earlier.
We can control when variables are treated as symbols versus evaluated (as already seen).
Use of $ allows us to "interpolate" values into the expression (as we've seen with printing in Notes 1).
a = 7;
expr2 = :($a+b)
                                   # `$a` interpolates. `b` is code.
expr3 = Expr(:call, :+, a, :b) # `a` is evaluated. `:b` is code.
:(7 + b)
expr3
:(7 + b)
a = 55
b = 999
eval(expr2)
1006
eval(expr3)
```

1006

Being able to control what is treated as code and what is treated as values is quite powerful when manipulating code expressions.
